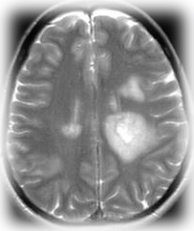
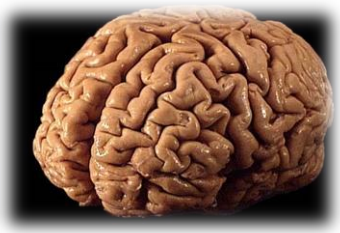
Vitamin D and MS

Gavin Giovannoni





Barts and The London School of Medicine and Dentistry

UCLPartners Academic Health Science Partnership

Latitude

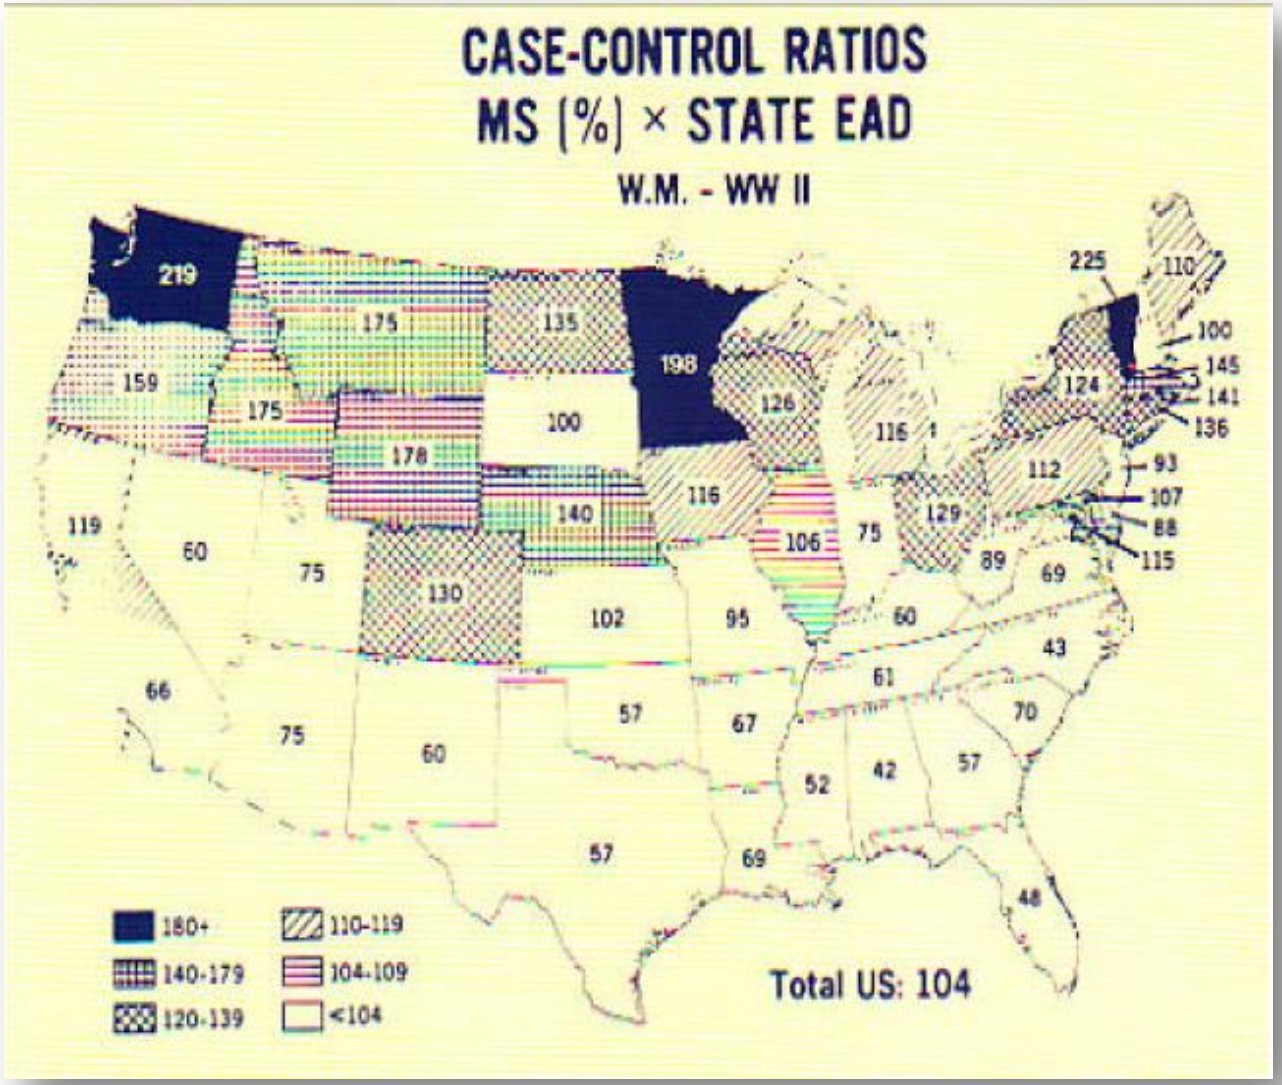
Geographical Distribution of MS

- First study of geographical distribution of MS prevalence by Davenport
- Key finding: Geographical variation in MS prevalence, implying population (genetic) and environmental contributions to MS risk

This article was published in *McAlpine's Multiple Sclerosis* 4th edition. Compston A. ed. London Churchill Livingstone Elsevier 2006;55 Fig 1.33 Copyright Elsevier (2007)

Davenport CB. In: *Association for Research in Nervous and Medical Conditions (ARNMD)*, vol 2. New York: Hoeber, 1921;pp8–19.

Prevalence of MS in the USA



Kurtzke et al, 1980

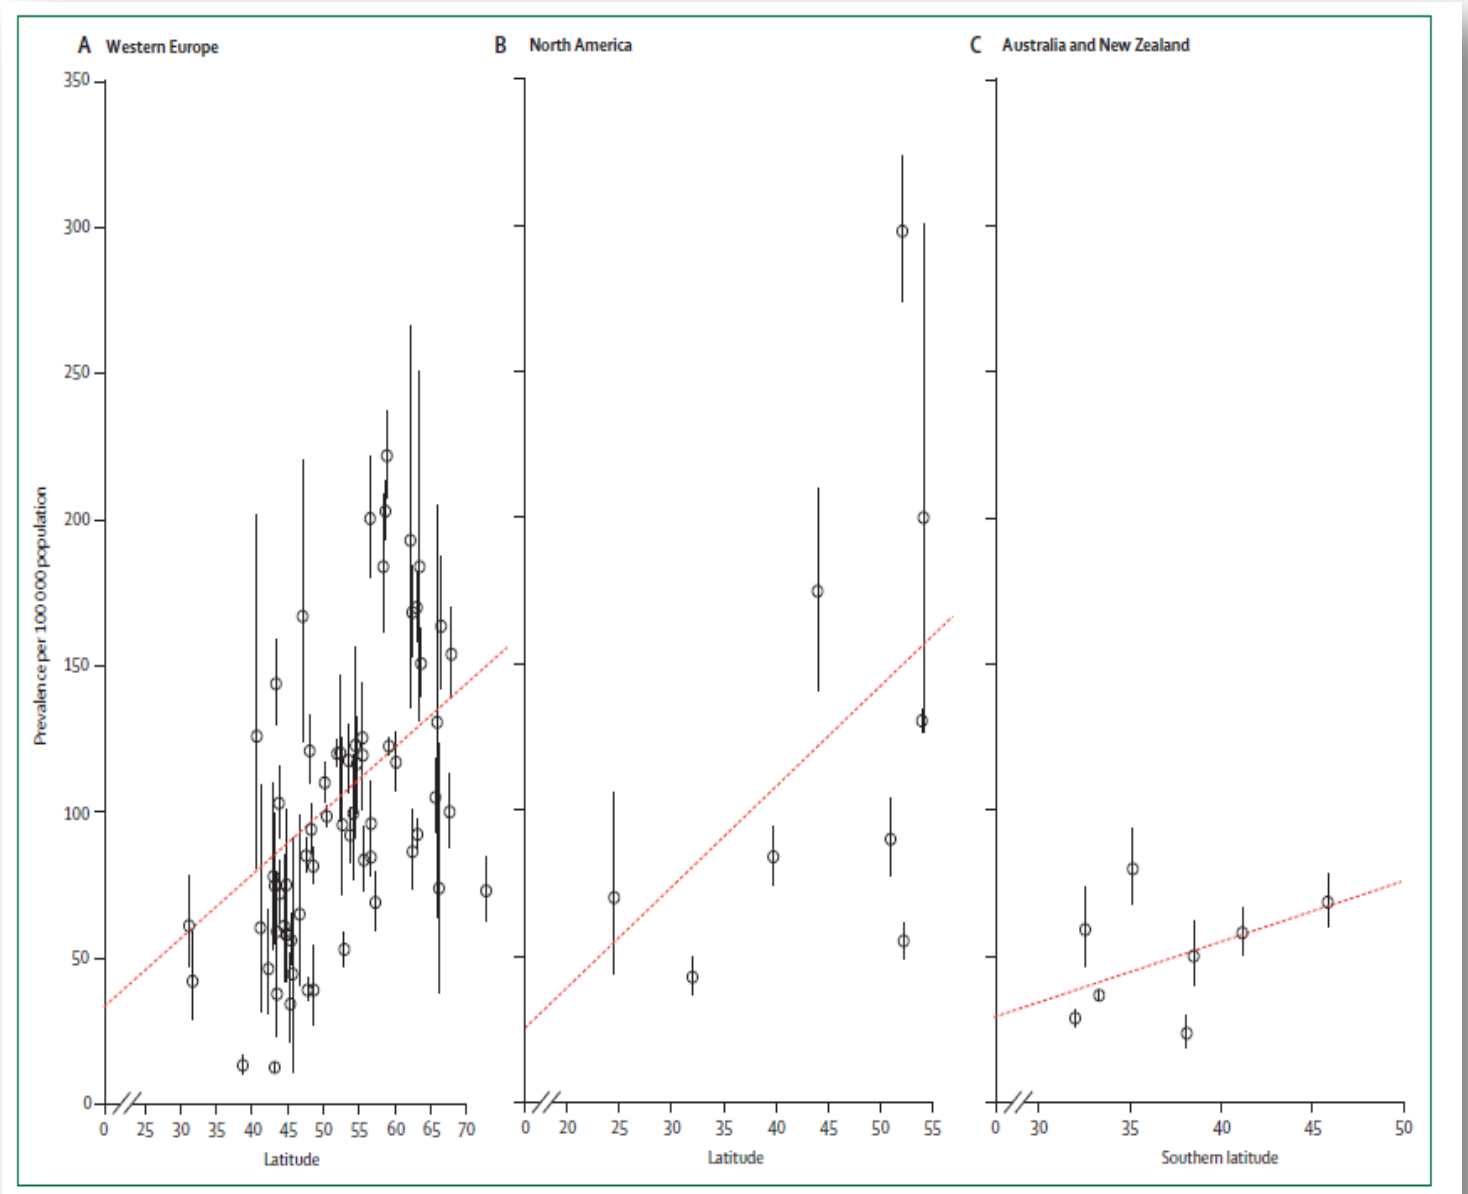


Figure 2: Prevalence by geographical latitude

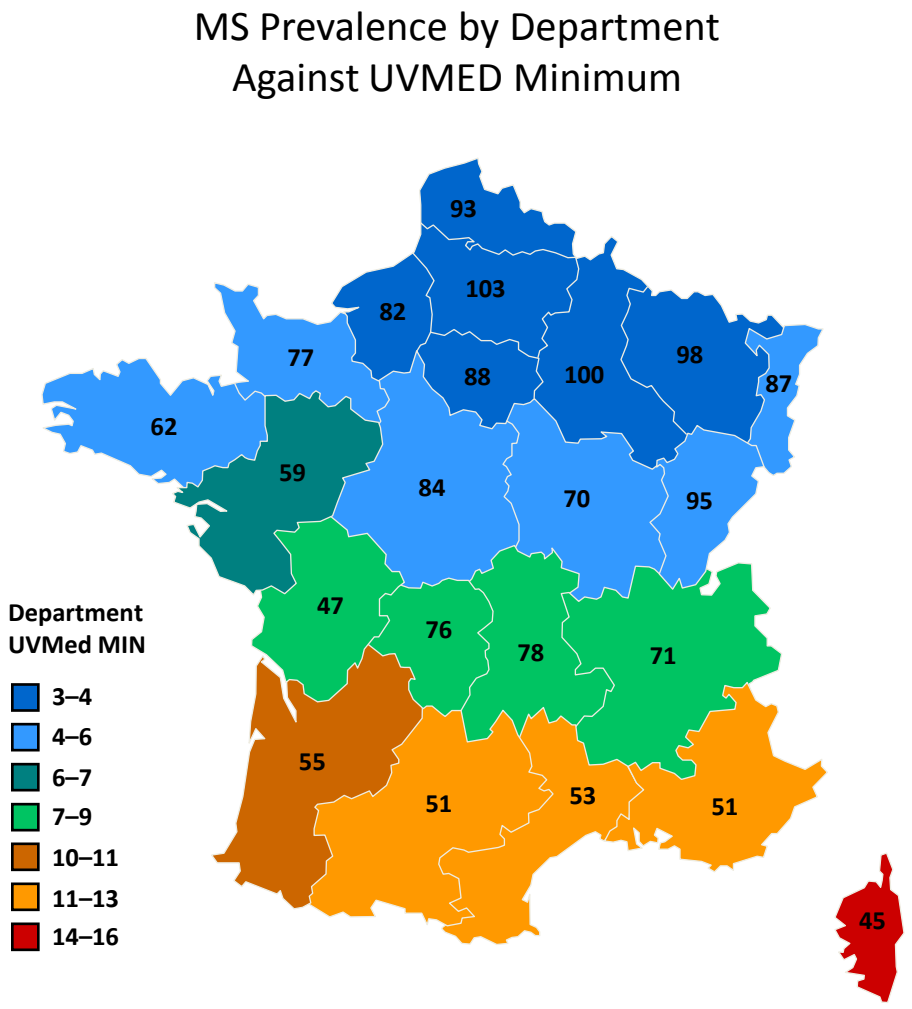
UVB and MS prevalence in France



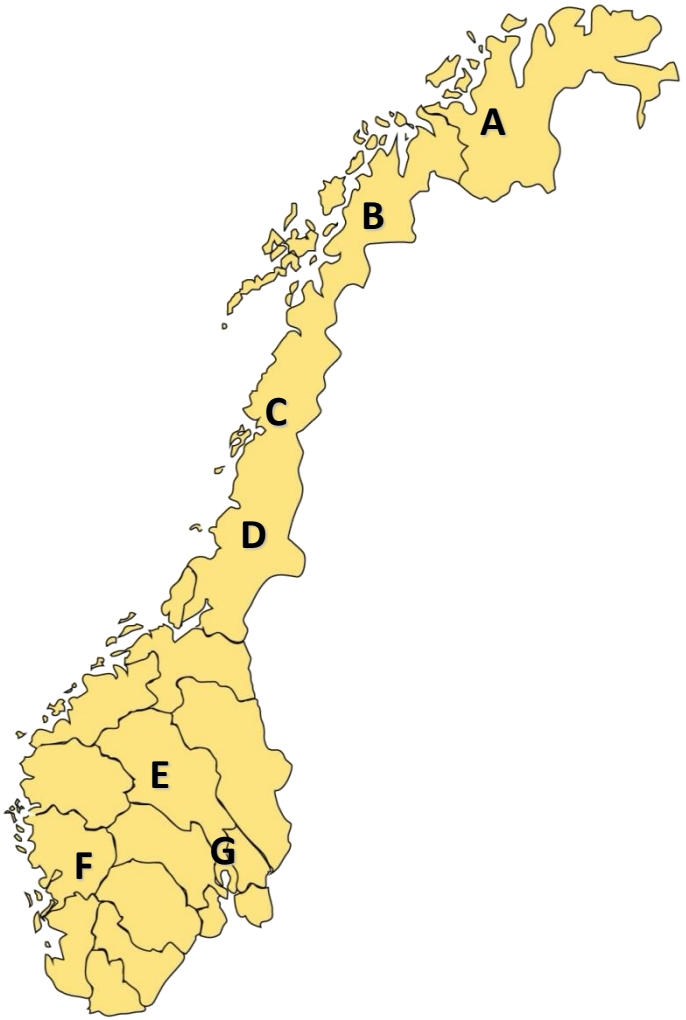
Orton et al. Neurology. 2011 Feb 1;76(5):425-31.

Prevalence of MS in Norway

- Prevalence data for counties in Norway (/10^5):

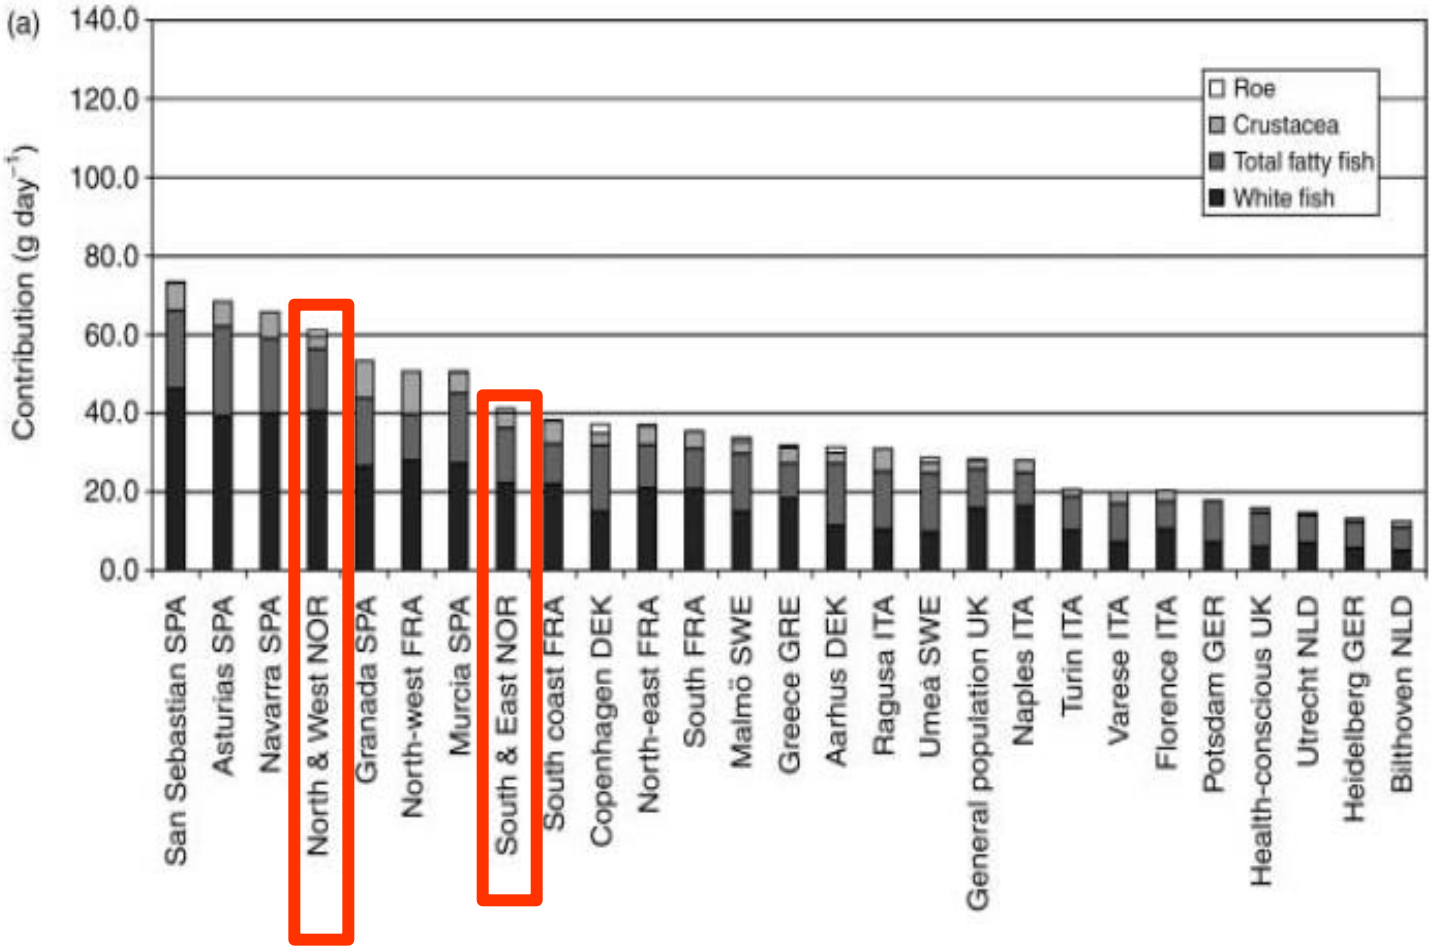
A Finnmark[1] (2003)	>83
B Troms[1] (2003)	>104
C Nordland (1999)	106
D Nord Trøndelag (1999)	164
E Oppland[2] (2002)	190
F Hordaland (2003)	151
G Oslo[2] (2005)	154

- In Norway, MS prevalence does not rise with increasing latitude, unlike other northern European countries and the USA
- As expected, measured UV radiation levels decrease with increasing latitude



Kampman et al, 2007

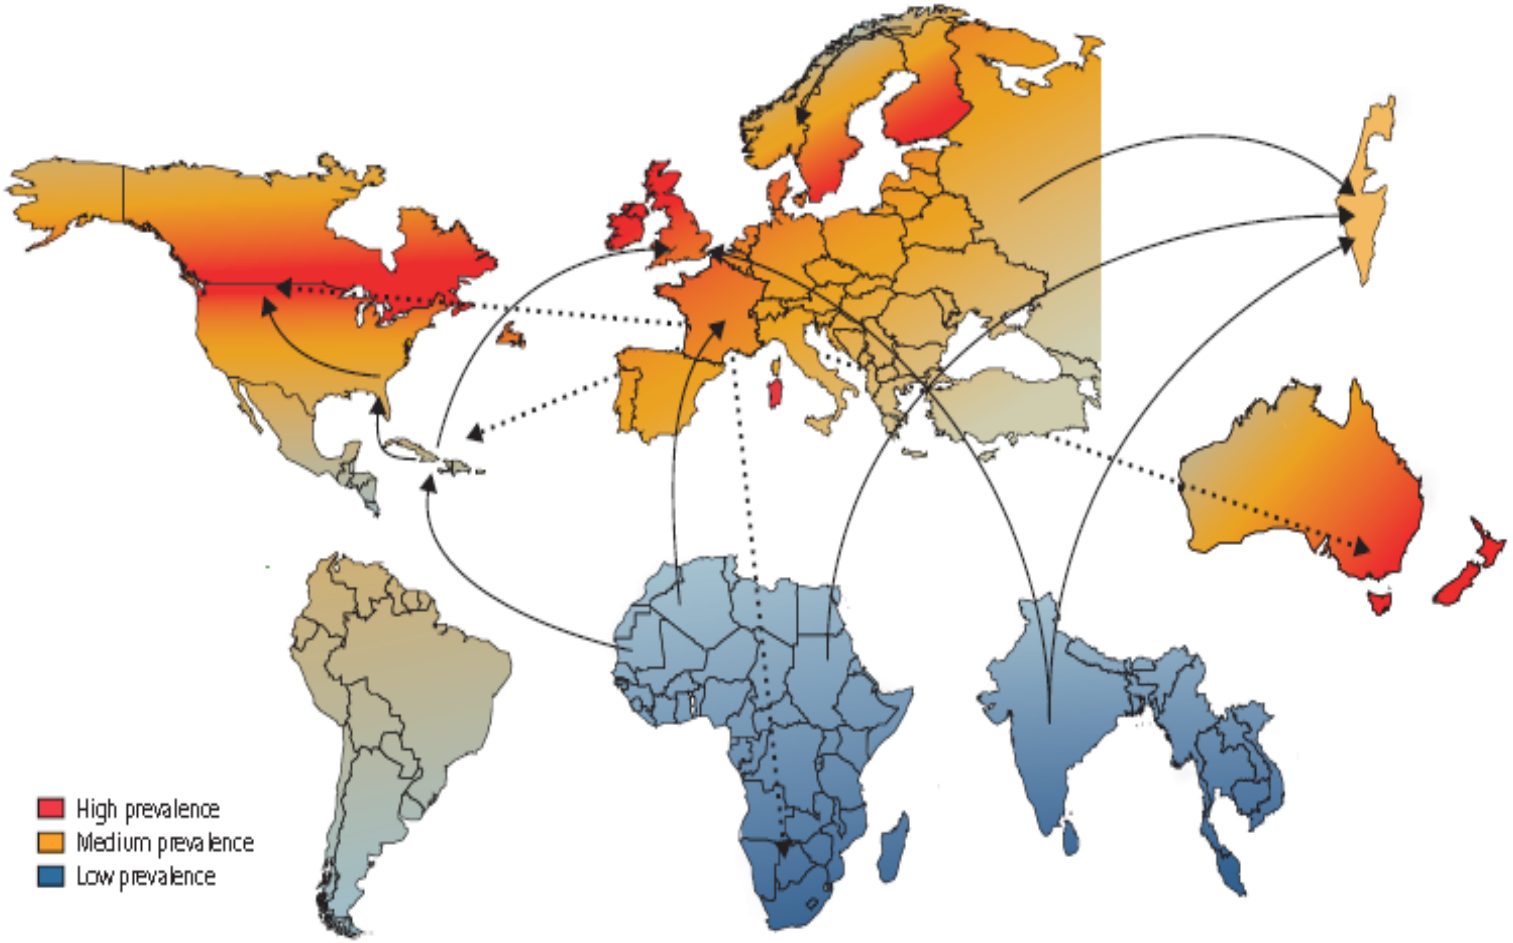
Fish consumption



Kampman et al, 2007

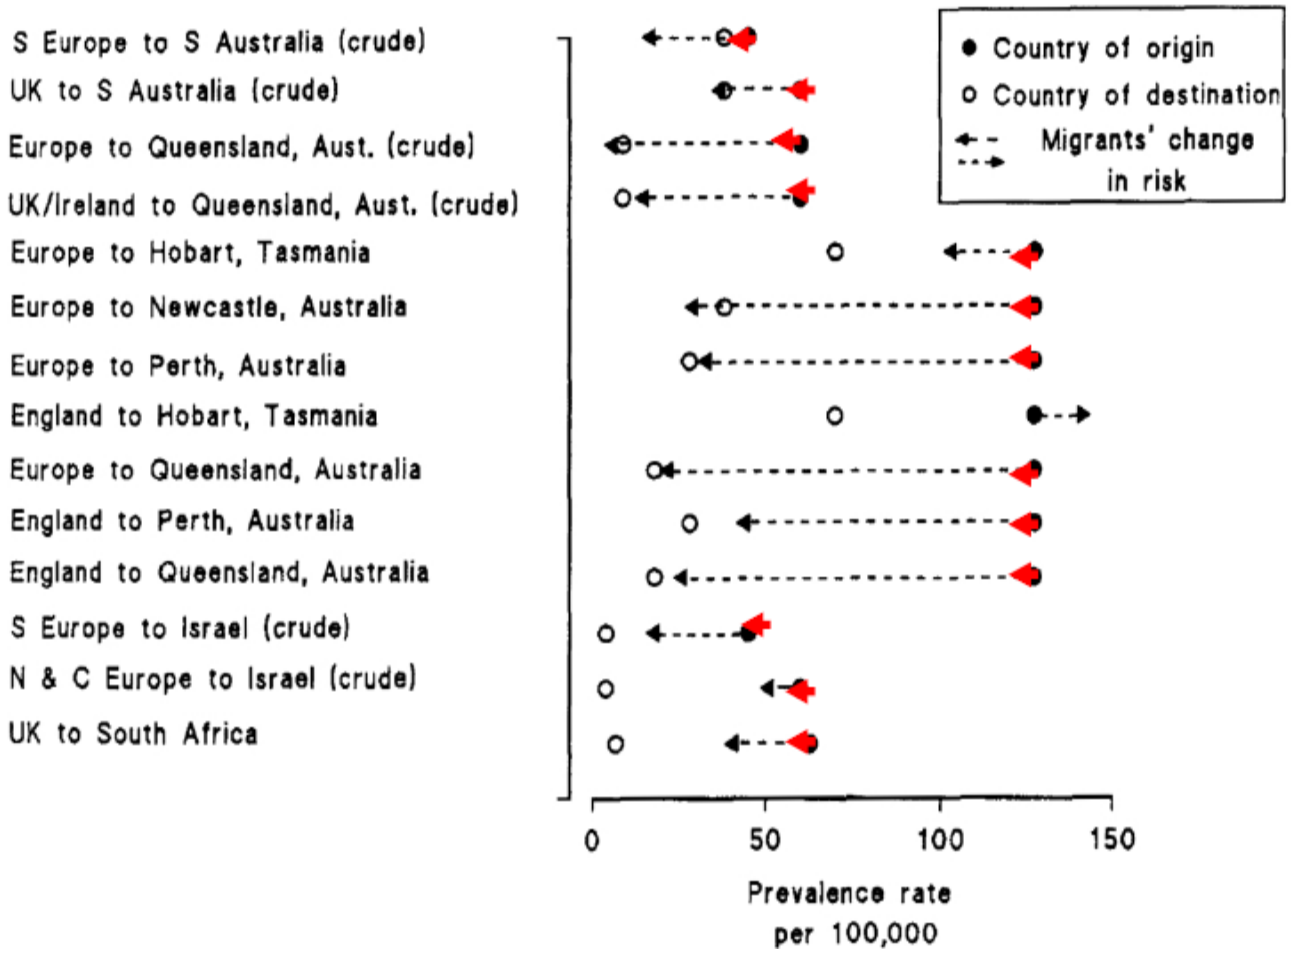
Migration

Migration studies



Compston & Coles, Lancet 2008.

The effect of migration on MS prevalence



Gale , 1995

Prevention

vD supplementation

Vitamin D and MS

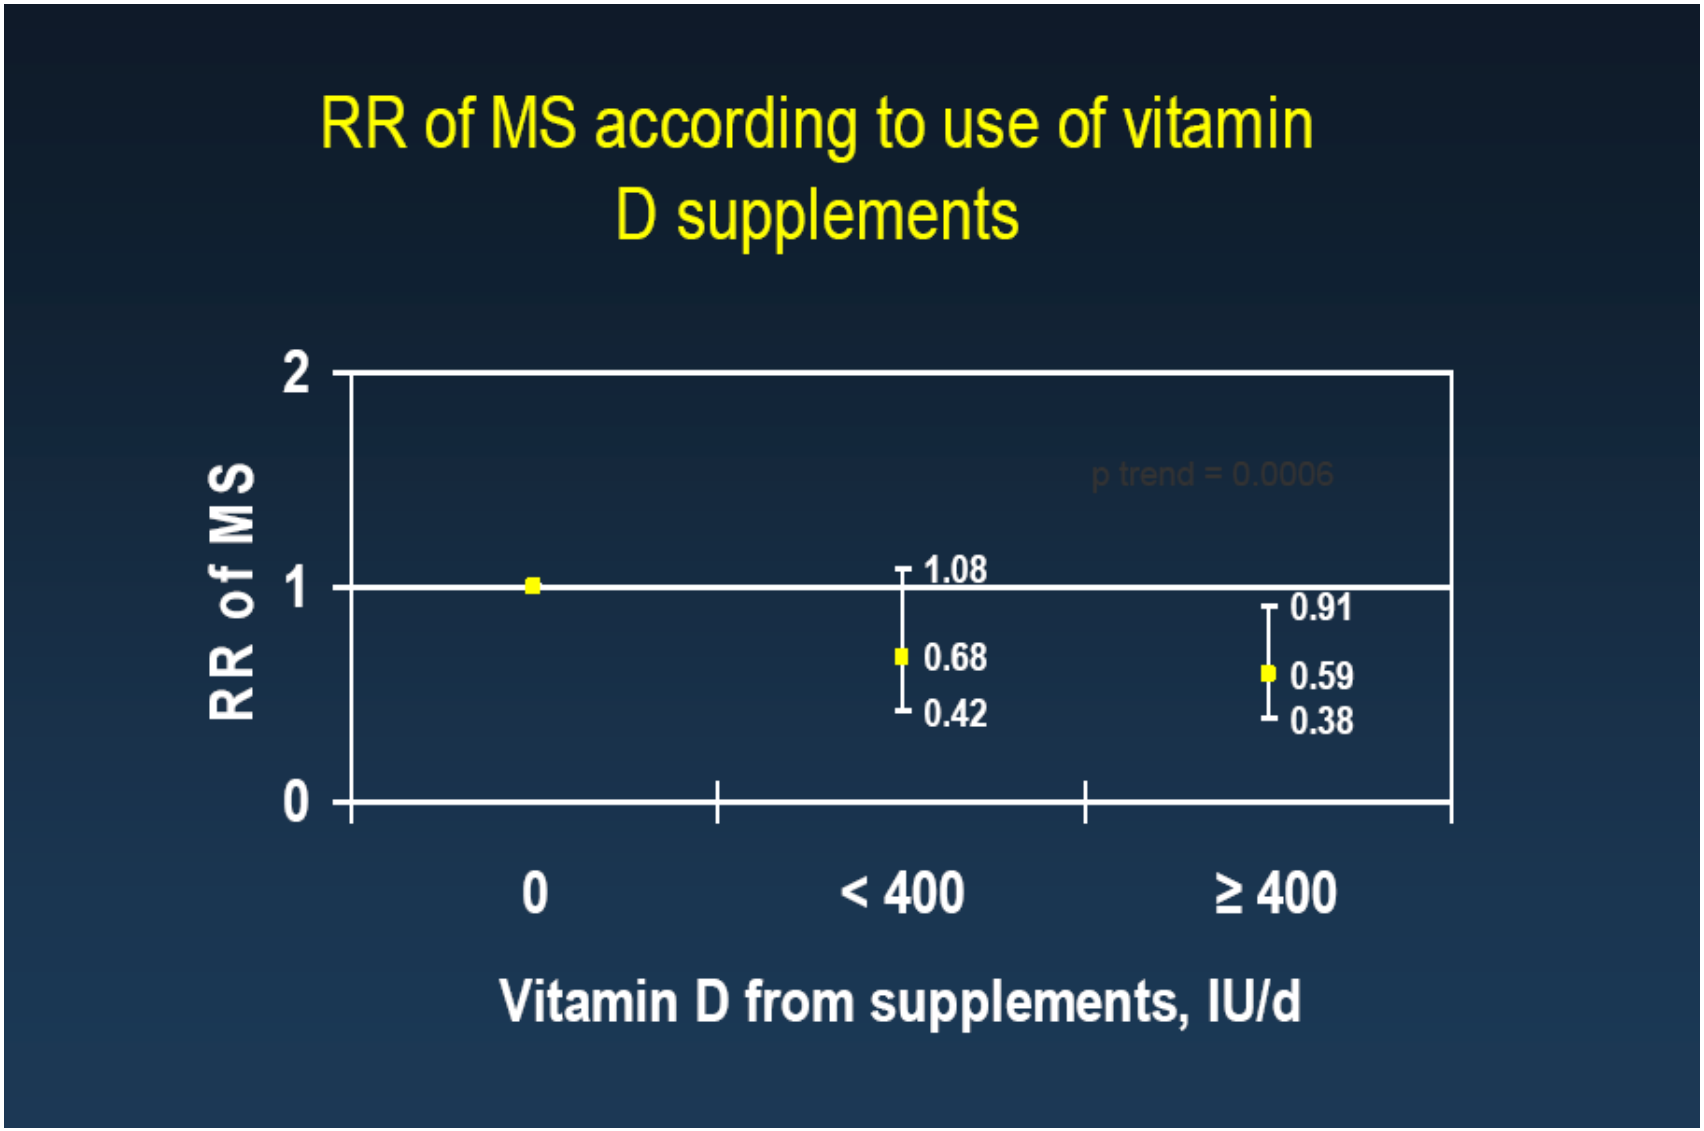
Vitamin D and MS

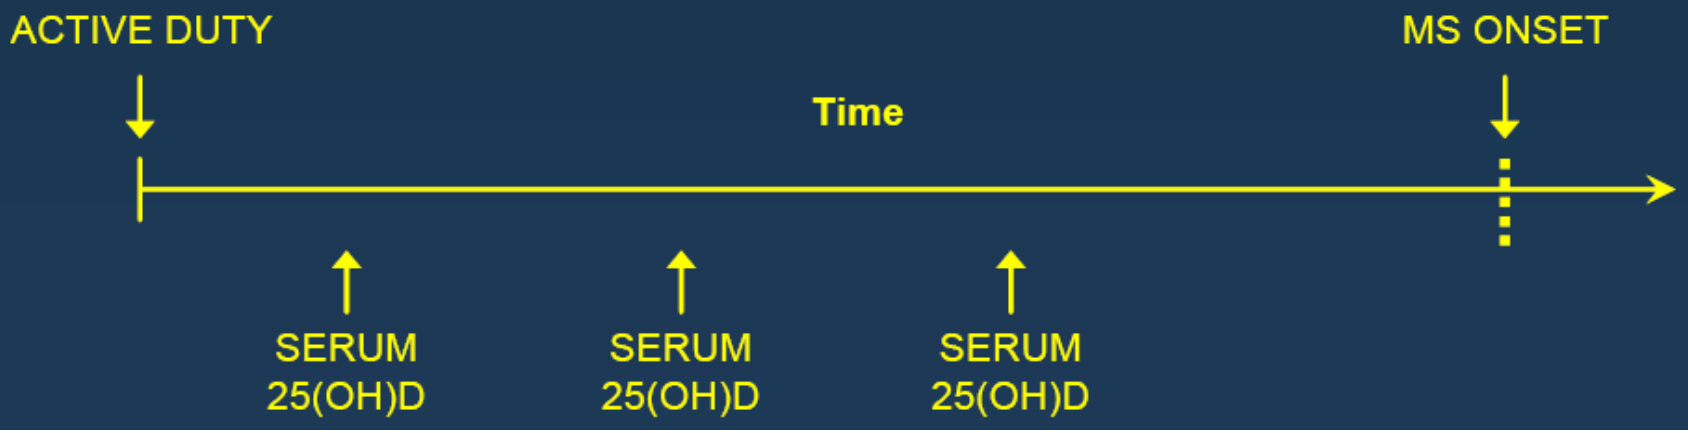


Munger et al, 2004

vD levels

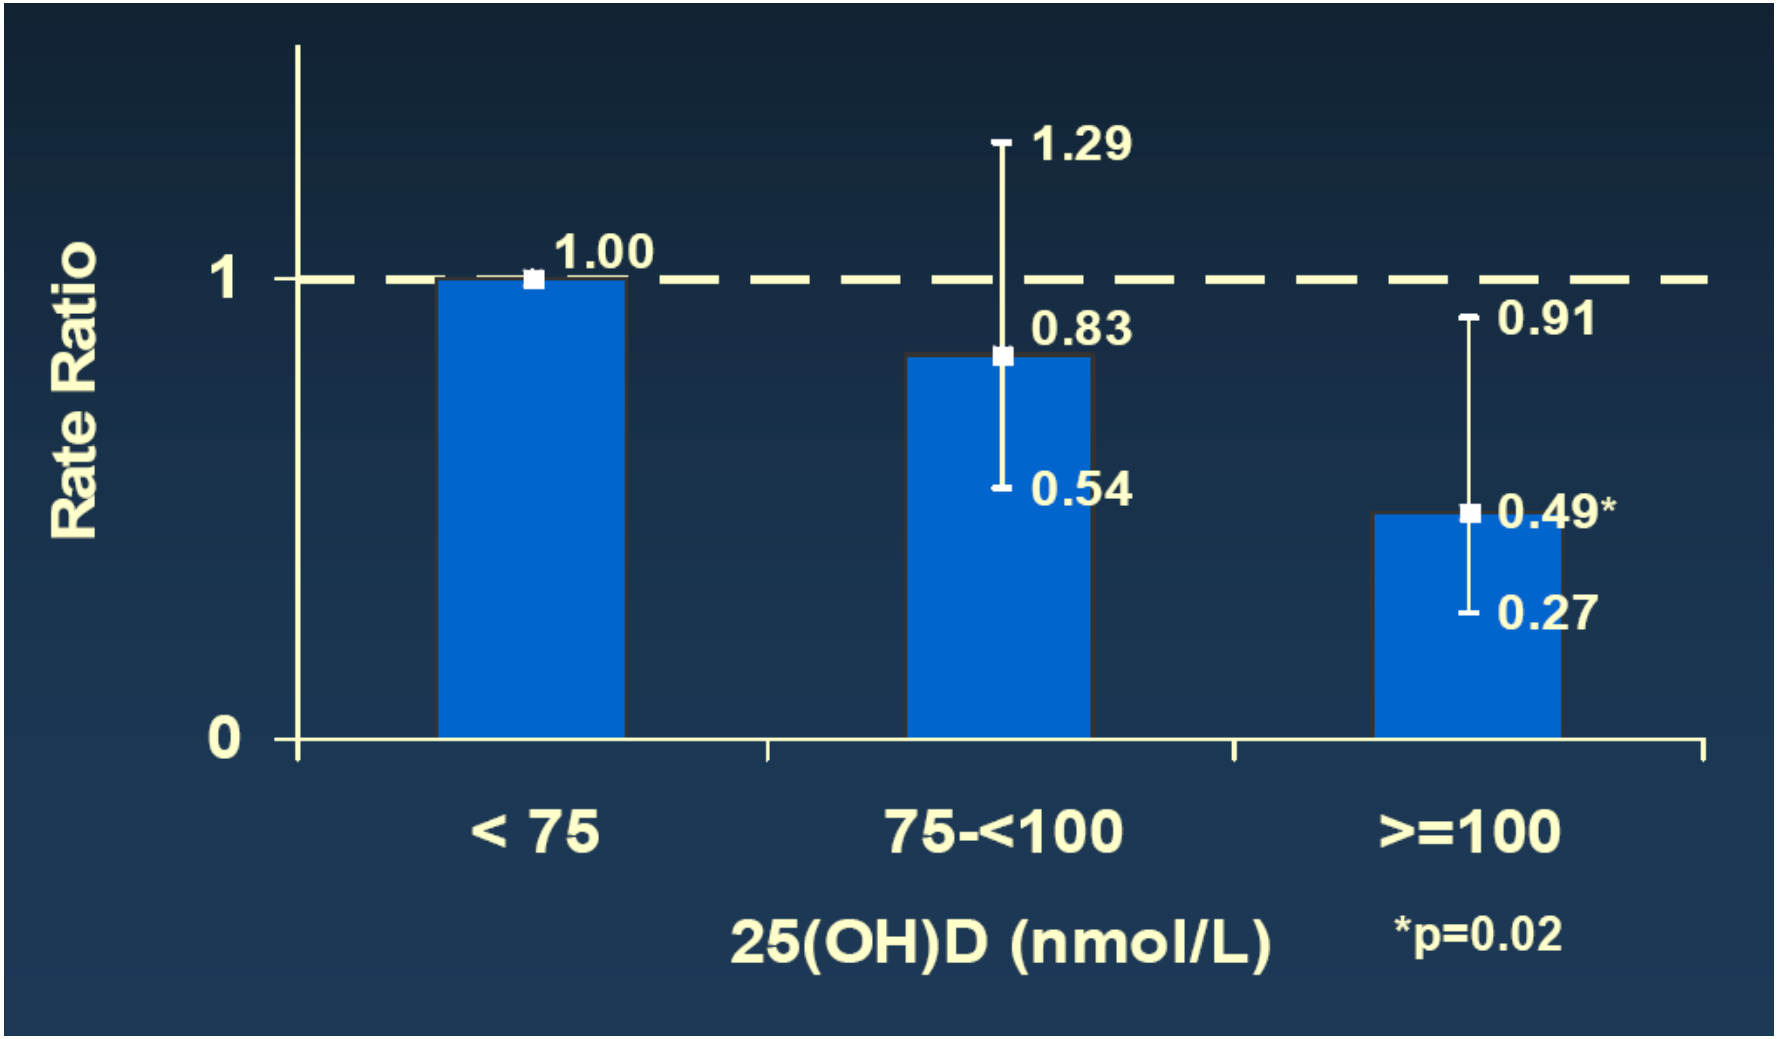
Vitamin D and MS

- >40 million serial blood samples since 1990 from over 8 million US military personnel
- Cases (n=257) identified via Physical Disability Agencies
- Controls (n=514) matched by age, sex, race/ethnicity, dates of blood collection



Munger et al, 2006

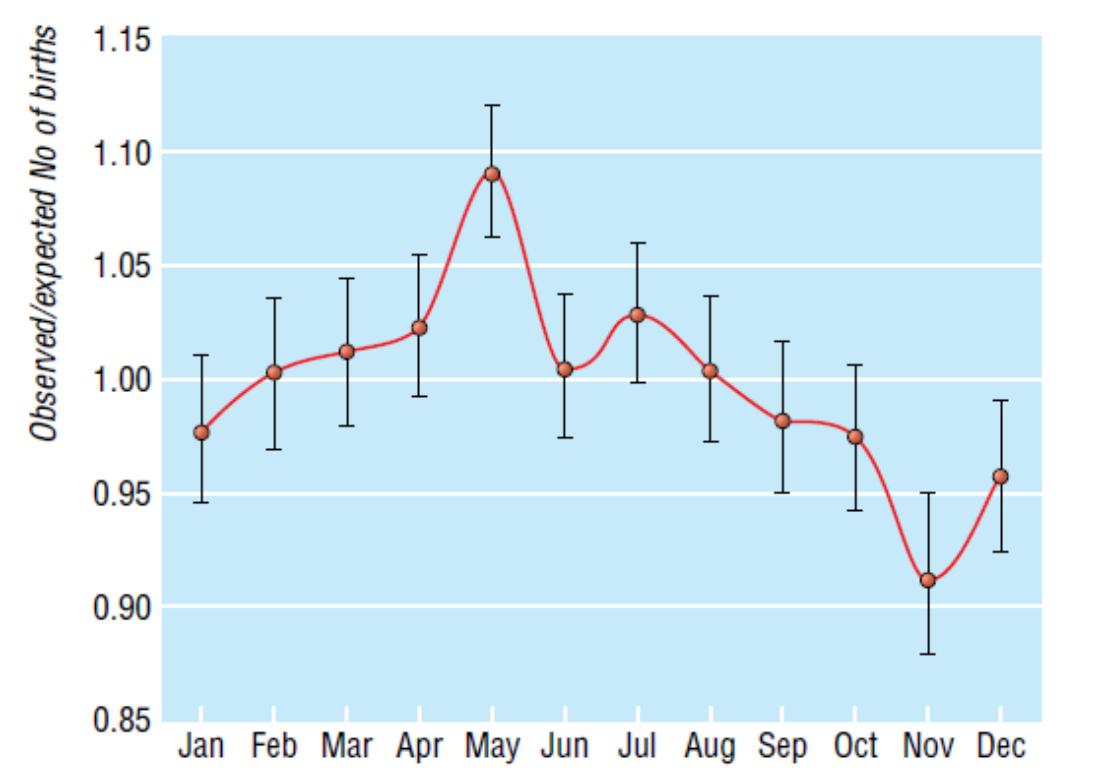
Vitamin D and MS



Munger et al, 2006

When to supplement?

Vitamin D and MS- Month of Birth



- Role of light exposure in MS supported by month of birth effect
- In northern hemisphere, significantly more people with MS are born in May (less light during pregnancy) than November (more light during pregnancy)
- Birth month effect is inverse in the southern hemisphere

Willer et al, 2005

Ramagopalan et al. BMC Neurol. 2012 Nov 5;12:135.

Conclusions

- MS prevention
  - Population health-based initiatives
  - Targeted high-risk population studies (children and siblings of people with MS)
- Low vD levels are associated with MS disease activity
  - relapses, disease progression and MRI activity (Gd, T2 and brain volume loss)
- Possible reverse causation
  - The consumptive hypovitaminosis hypothesis
  - Arguments against consumptive hypovitaminosis hypothesis
    - Worldwide MS epidemiology (latitude, migration, sex ratio, changing incidence, MoB effects)
    - Seasonal variation of MS onset and disease activity
  - Current evidence-base regarding treatment is unconvincing
  - We need large well-controlled randomised clinical trials (easier said than done)
- We need more basic science to support the causation theory
- What dose?
  - Evolutionary medicine suggests we need to target a blood plasma level above 100nmol/L
- What advice?
  - To supplement to achieve a year long blood levels of > 100-120 nmol/L
  - In the UK we can't rely on diet or sun exposure to achieve these levels
  - EFSA or Vitamin D council recommendations
- Don't forget bone health as a justification to act now

SCIENTIFIC OPINION

Scientific Opinion on the Tolerable Upper Intake Level of vitamin D[1]

EFSA Panel on Dietetic Products, Nutrition and Allergies (NDA)[2, 3]

European Food Safety Authority (EFSA), Parma, Italy

ABSTRACT

Following a request from the European Commission, the Panel on Dietetic Products, Nutrition and Allergies was asked to re-evaluate the safety in use of vitamin D and to provide, if necessary, revised Tolerable Upper Intake Levels (ULs) of vitamin D for all relevant population groups. The ULs for adults including pregnant and lactating women, children and adolescents were revised. For adults, hypercalcaemia was selected as the indicator of toxicity. In two studies in men, intakes between 234 and 275 µg/day were not associated with hypercalcaemia, and a no observed adverse effect level (NOAEL) of 250 µg/day was established. Taking into account uncertainties associated with these studies, the UL for adults including pregnant and lactating women was set at 100 µg/day. Despite a continuing paucity of data for high vitamin D intakes in children and adolescents, the UL was adapted to 100 µg/day for ages 11-17 years, considering that owing to phases of rapid bone formation and growth this age group is unlikely to have a lower tolerance for vitamin D compared to adults. The same applies also to children aged 1-10 years, but taking into account their smaller body size, a UL of 50 µg/day is proposed. For infants, the UL of 25 µg/day based on previously available data relating high vitamin D intakes to impaired growth and hypercalcaemia was retained as limited additional evidence has emerged since the previous risk assessment. Data on vitamin D intakes from surveys in 14 European countries indicate that intakes in high consumers are below the revised ULs for vitamin D for all population groups.

How much vitamin D do I need to take?

Different organizations recommend different daily intakes. Here are the recommendations from some organizations in the United States:

Recommended daily intakes from various organizations:

	Vitamin D Council	Endocrine Society	Food and Nutrition Board
Infants	1,000 IU/day	400-1,000 IU/day	400 IU/day
Children	1,000 IU/day per 25lbs of body weight	600-1,000 IU/day	600 IU/day
Adults	5,000 IU/day	1,500-2,000 IU/day	600 IU/day, 800 IU/day for seniors

The Food and Nutrition Board recommended daily intakes are the official recommendations by the United States government.

Why are the recommendations so different? Some researchers believe that there isn't enough evidence to support taking higher amounts of vitamin D yet. On the other hand, some researchers believe that research is proving, or will prove, that taking lower amounts isn't enough.

Summary

Background Vitamin D is crucial for maintenance of musculoskeletal health, and might also have a role in extraskeletal tissues. Determinants of circulating 25-hydroxyvitamin D concentrations include sun exposure and diet, but high heritability suggests that genetic factors could also play a part. We aimed to identify common genetic variants affecting vitamin D concentrations and risk of insufficiency.

Methods We undertook a genome-wide association study of 25-hydroxyvitamin D concentrations in 33 996 individuals of European descent from 15 cohorts. Five epidemiological cohorts were designated as discovery cohorts (n=16 125), five as in-silico replication cohorts (n=9367), and five as de-novo replication cohorts (n=8504). 25-hydroxyvitamin D concentrations were measured by radioimmunoassay, chemiluminescent assay, ELISA, or mass spectrometry. Vitamin D insufficiency was defined as concentrations lower than 75 nmol/L or 50 nmol/L. We combined results of genome-wide analyses across cohorts using *Z*-score-weighted meta-analysis. Genotype scores were constructed for confirmed variants.

Findings Variants at three loci reached genome-wide significance in discovery cohorts for association with 25-hydroxyvitamin D concentrations, and were confirmed in replication cohorts: 4p12 (overall $p=1\cdot9\times10^{-109}$ for rs2282679, in *GC*); 11q12 ($p=2\cdot1\times10^{-27}$ for rs12785878, near *DHCR7*); and 11p15 ($p=3\cdot3\times10^{-20}$ for rs10741657, near *CYP2R1*). Variants at an additional locus (20q13, *CYP24A1*) were genome-wide significant in the pooled sample ($p=6\cdot0\times10^{-10}$ for rs6013897). Participants with a genotype score (combining the three confirmed variants) in the highest quartile were at increased risk of having 25-hydroxyvitamin D concentrations lower than 75 nmol/L (OR 2·47, 95% CI 2·20–2·78, $p=2\cdot3\times10^{-48}$) or lower than 50 nmol/L (1·92, 1·70–2·16, $p=1\cdot0\times10^{-26}$) compared with those in the lowest quartile.

Interpretation Variants near genes involved in cholesterol synthesis, hydroxylation, and vitamin D transport affect vitamin D status. Genetic variation at these loci identifies individuals who have substantially raised risk of vitamin D insufficiency.

Funding Full funding sources listed at end of paper (see Acknowledgments).

Introduction

Vitamin D insufficiency affects as many as half of otherwise healthy adults in developed countries.[1] The musculoskeletal consequences of inadequate vitamin D concentrations are well established, and include childhood rickets, osteomalacia, and fractures.[2] A growing number of other disorders have also been linked to vitamin D insufficiency, although causal associations

Personal, social, and cultural factors are important determinants of vitamin D availability via their effects on sun exposure and diet. Sufficient exposure to ultraviolet light or adequate intake from diet or supplements is needed to maintain vitamin D status. Concentrations of the widely accepted biomarker for vitamin D, 25-hydroxyvitamin D, are highest in the summer and lowest in the winter in northern latitudes. However, only
