## Abstract

Zika virus was discovered in Uganda in 1947 and is transmitted by *Aedes* mosquitoes, which also act as vectors for dengue and chikungunya viruses throughout much of the tropical world. In 2007, an outbreak in the Federated States of Micronesia sparked public health concern. In 2013, the virus began to spread across other parts of Oceania and in 2015, a large outbreak in Latin America began in Brazil. Possible associations with microcephaly and Guillain-Barré syndrome observed in this outbreak have raised concerns about continued global spread of Zika virus, prompting its declaration as a Public Health Emergency of International Concern by the World Health Organization. We conducted species distribution modelling to map environmental suitability for Zika. We show a large portion of tropical and sub-tropical regions globally have suitable environmental conditions with over 2.17 billion people inhabiting these areas.

## Impact Statement

This global map of environmental suitability for Zika virus and the estimated population living at potential risk can help refine public health guidelines, travel advisories, and intervention strategies at a crucial time in the global spread of this arbovirus.

## Introduction

Zika virus (ZIKV) is an emerging arbovirus carried by mosquitoes of the genus *Aedes* (Musso, Nilles and Cao-Lormeau 2014). Although discovered in Uganda in 1947 (Dick 1952, Dick 1953), ZIKV was only known to cause sporadic infections in humans in Africa and Asia until 2007 (Lanciotti et al. 2008), when it caused a large outbreak of symptomatic cases on Yap island in the Federated States of Micronesia (FSM), followed by another in French Polynesia in 2013-14 and subsequent spread across Oceania (Musso, Cao-Lormeau and Gubler 2015a). In the 2007 Yap island outbreak, it was estimated that approximately 20% of ZIKV cases were symptomatic. While indigenous transmission of ZIKV to humans was reported for the first time in Latin America in 2015 (Zanluca et al. 2015, WHO 2015), recent phylogeographic research estimates that the virus was introduced into the region between May and December 2013 (Faria et al. 2016). This recent rapid spread has led to concern that the virus is following a similar pattern of global expansion to that of dengue and chikungunya (Musso et al. 2015a).

52

53 ZIKV has been isolated from 19 different *Aedes* species (Haddow et al. 2012, Grard et al. 2014),  
54 but virus has been most frequently found in *Ae. aegypti* (Monlun et al. 1992, Marchette, Garcia  
55 and Rudnick 1969, Smithburn 1954, Pond 1963, Faye et al. 2008, Foy et al. 2011b, Dakar 1999).  
56 These studies were based upon ancestral African strains of ZIKV, but the current rapid spread of  
57 ZIKV in Latin America is indicative of this highly efficient arbovirus vector (Marcondes and  
58 Ximenes 2015). The relatively recent global spread of *Ae. albopictus* (Benedict et al. 2007,  
59 Kraemer et al. 2015c) and the rarity of ZIKV isolations from wild mosquitoes may also partially  
60 explain the lower frequency of isolations from *Ae. albopictus* populations. Whilst virus  
61 transmission by *Ae. albopictus* and other minor vector species has normally resulted in only a  
62 small number of cases (Kutsuna et al. 2015, Roiz et al. 2015), these vectors do pose the threat  
63 of limited transmission (Grard et al. 2014). The wide geographic distribution of *Ae. albopictus*  
64 combined with the frequent virus introduction *via* viraemic travellers (McCarthy 2016, Bogoch et  
65 al. 2016, Morrison et al. 2008, Scott and Takken 2012), means the risk for ZIKV infection *via* this  
66 vector must therefore also be considered in ZIKV mapping.

67

68 The fact that ZIKV reporting was limited to a few small areas in Africa and Asia until 2007 means  
69 that global risk mapping has not, until recently, been a priority (Pigott et al. 2015b). Recent  
70 associations with Guillain-Barré syndrome in adults and microcephaly in infants born to ZIKV-  
71 infected mothers (World Health Organization 2015, Martines et al. 2016) have revealed that ZIKV  
72 could lead to more severe complications than the mild rash and flu-like symptoms that  
73 characterize the majority of symptomatic cases (Gatherer and Kohl 2015). Considering these  
74 potentially severe complications and the rapid expansion of ZIKV into previously unaffected  
75 areas, the global public health community needs information about those areas that are  
76 environmentally suitable for transmission of ZIKV to humans. Being a closely related flavivirus to  
77 DENV, there is furthermore the potential for antigen-based diagnostic tests to exhibit cross-  
78 reactivity when IgM ELISA is used for rapid diagnosis. Although ZIKV-specific serologic assays  
79 are being developed by the U.S. Centers for Disease Control, currently the only method of  
80 confirming ZIKV infection is by using PCR on acute specimens (Lanciotti et al. 2008, Faye et al.  
81 2008). Awareness of suitability for transmission is essential if proper detection methods are to be  
82 employed.

83

84 In this paper, we use species distribution modelling techniques that have been useful for  
85 mapping other vector-borne diseases such as dengue (Bhatt et al. 2013), Leishmaniasis (Pigott  
86 et al. 2014b), and Crimean-Congo Haemorrhagic Fever (Messina et al. 2015b) to map  
87 environmental suitability for ZIKV. The environmental niche of a disease can be identified  
88 according to a combination of environmental conditions supporting its presence in a particular  
89 location, with statistical modelling then allowing this niche to be described quantitatively  
90 (Kraemer et al. 2016). Niche modelling uses records of known disease occurrence alongside  
91 hypothesized environmental covariates to predict suitability for disease transmission in regions  
92 where it has yet to be reported (Elith and Leathwick 2009). Contemporary high spatial-resolution  
93 global data representing a variety of environmental conditions allows for these predictions to be  
94 made at a global scale (Hay et al. 2006).

95

## 96 **Results**

97 Figure 1a shows the locations of the 323 standardized occurrence records in the final dataset,  
98 classified by the following date ranges: (i) up until 2006 (before the outbreak in FSM); (ii)  
99 between 2007 (the year of the FSM outbreak) and 2014; and (iii) since 2015, the first reporting of  
100 ZIKV in the Americas. This map is accompanied by the graph in Figure 1b, showing the number  
101 of reported occurrence locations globally by year. These figures highlight the more sporadic

102 nature of reporting until recent years, with the majority of occurrences in the dataset (63%)  
103 coming from the recent 2015-2016 outbreak in Latin America.

104  
105 The final map that resulted from the mean of 300 ensemble Boosted Regression Tree (BRT)  
106 models is shown in Figure 2a (with greater detail shown for each region in Figures 2b-2d). Figure  
107 2 -- figure supplement 1 shows the distribution of uncertainty based upon the upper and lower  
108 prediction quantiles from the 300 models. We restricted our models to make predictions only  
109 within areas where i) mosquito vectors (in this case *Ae. aegypti*) were able to persist and ii)  
110 where temperature was sufficient for arboviral replication within the mosquito. The former of  
111 these was calculated by taking the *Ae. aegypti* probability of occurrence (Kraemer *et al.* 2015c)  
112 value that incorporated 90% of all known occurrences (Kraemer *et al.* 2015b) (giving a threshold  
113 value of 0.8 and greater) while the latter was evaluated using a mechanistic mosquito model  
114 (Brady *et al.* 2013, Brady *et al.* 2014), which identified regions where arboviral transmission could  
115 be sustained for at least 355 days (one year minus the human incubation period) in an average  
116 year. Figure 3 is a country-level map distinguishing between those countries that are currently  
117 reporting ZIKV, those which have reported ZIKV in the past, those which have highly suitable  
118 areas for transmission, and those which are unsuitable. Our models predicted high levels of risk  
119 for ZIKV in many areas within the tropical and sub-tropical zones. Large portions of the Americas  
120 are suitable for transmission, with the largest areas of risk occurring in Brazil, followed by  
121 Colombia and Venezuela, all of which have reported high numbers of cases in the 2015-2016  
122 outbreak. In Brazil, where the highest numbers of ZIKV are reported in the ongoing epidemic, the  
123 coastal cities in the south as well as large areas of the north are identified to have the highest  
124 environmental suitability of ZIKV. The central region of Brazil, on the other hand, has low  
125 population densities and smaller mosquito populations, which is reflected in the relatively low  
126 suitability for ZIKV transmission seen in the map. Although ZIKV has yet to be reported in the  
127 USA, a large portion of the southeast region of the country, including much of Texas through to  
128 Florida, is also highly suitable for transmission. Potential risk for ZIKV transmission is high in  
129 much of sub-Saharan Africa, with continuous suitability in the Democratic Republic of Congo and  
130 surrounding areas and several sporadic case reports in western sub-Saharan countries since the  
131 1950s. Although no symptomatic cases have yet been reported in India, a large portion of this  
132 country is at potential risk for ZIKV transmission (over 2 million square kilometres), with  
133 environmental suitability extending from its northwest regions through to Bangladesh and  
134 Myanmar. The Indochina region, southeast China, and Indonesia all have large areas of  
135 environmental suitability as well, extending into Oceania. While only representing less than ten  
136 percent of Australia's total land area, the area shown to be suitable for ZIKV transmission in its  
137 northernmost regions is considerable (comprising nearly 250,000 square kilometres).

138  
139 Our models showed ZIKV risk to be particularly influenced by annual cumulative precipitation,  
140 contributing 65.0% to the variation in the ensemble of models. The next most important predictor  
141 in the model was temperature suitability for DENV transmission *via Ae. albopictus*, contributing  
142 14.6%. These are followed by urban extents (8.3%), temperature suitability for DENV *via Ae.*  
143 *aegypti* (5.7%), the Enhanced Vegetation Index (EVI; 3.8%), and minimum relative humidity  
144 (2.5%). Effect plots for each covariate are provided in Figure 2 -- figure supplement 2. Validation  
145 statistics indicated high predictive performance of the BRT ensemble mean map evaluated in a  
146 10-fold cross-validation procedure, with area under the receiver operating characteristic (AUC) of  
147 0.829 ( $\pm 0.121$  SD). Due to the uncertainty about *Ae. albopictus* as a competent vector for ZIKV,  
148 we also provide results for an ensemble of models which did not include temperature suitability  
149 for dengue *via* this mosquito species in Figure 2 -- figure supplement 3.

150

151 A threshold environmental suitability value of 0.397 in our final map was determined to  
152 incorporate 90% of all ZIKV occurrence locations. This was used to classify each 5km x 5km  
153 pixel on our final map as suitable or unsuitable for ZIKV transmission to humans. Using high-  
154 resolution global population estimates (WorldPop 2015, SEDAC 2015), we summed the  
155 populations living in Zika-suitable areas and have identified 2.17 billion people globally living  
156 within areas that are environmentally suitable for ZIKV transmission. Table 1 shows a breakdown  
157 of this figure by major world region, also showing the top four contributing countries to the  
158 potential population at risk. Asia has the most people living in areas that are suitable for ZIKV  
159 transmission at 1.42 billion, accounted for in large part by those living in India. In Africa, roughly  
160 453 million people are living in areas suitable for ZIKV transmission, the largest proportion of  
161 which live in Nigeria. In the Americas, more than 298 million people live in ZIKV-suitable  
162 transmission zones, with approximately 40 percent of these people living in Brazil. Within the  
163 majority of environmentally suitable areas for ZIKV in the Americas, prolonged year-round  
164 transmission is possible. Southern Brazil and Argentina, however, are more likely to see  
165 transmission interrupted throughout the year, as is the case with the USA should autochthonous  
166 ZIKV transmission occur there. Using high-resolution data on births for the year 2015 (WorldPop  
167 2015), we also estimate that 5.42 million births will occur in the Americas over the next year  
168 within areas and times of environmental suitability for ZIKV transmission.

169

## 170 **Discussion**

171 A large number of viruses (circa 219) are known to be pathogenic (Woolhouse et al. 2012). Of  
172 the 53 species of *Flavivirus*, 19 are reported to have caused illness in humans (ICTV 2014).  
173 Some flaviviruses, such as DENV, YFV, Japanese encephalitis virus, and West Nile virus, are  
174 widespread, causing many thousands of infections each year. The remainder, however, have  
175 been recognized as being pathogenic to humans for decades, but have highly focal reported  
176 distributions and are only minor contributors to mortality and disability globally (Hay et al. 2013,  
177 Murray et al. 2015). As a result, many are of relatively low priority when research and policy  
178 interest are considered (Pigott et al. 2015b). The recent spread of ZIKV across the globe  
179 highlights the need to reassess our consideration of these other flaviviruses, to gain a better  
180 understanding of the factors driving their spread and the potential for geographic expansion  
181 beyond their currently limited geographical extents.

182

183 Environmental suitability for virus transmission in an area does not necessarily mean that it will  
184 arrive and/or establish in that location. Arboviral infections in particular are dependent on a  
185 variety of non-environmental factors, with their movement having historically been largely  
186 attributed to human mobility from travel, trade, and migration, which introduce the viruses to  
187 places where mosquito vectors are already present (Murray, Quam and Wilder-Smith 2013,  
188 Weaver and Reisen 2010, Nunes et al. 2015, Gubler and Clark 1995). The identification of  
189 locations with permissible environments for transmission of emerging diseases like ZIKV is  
190 crucial, as importation could give rise to subsequent autochthonous cases in these locations  
191 (Hennessey, Fischer and Staples 2016, Zanluca et al. 2015). In order to identify places  
192 potentially receptive for ZIKV, we assembled the first comprehensive spatial dataset for ZIKV  
193 occurrence in humans and compiled a comprehensive set of high-resolution environmental  
194 covariates. We then used these data to implement a species distribution modelling approach  
195 (Elith and Leathwick 2009) that has proven useful for mapping other vector-borne diseases  
196 (Bhatt et al. 2013, Pigott et al. 2014a, Mylne et al. 2015, Messina et al. 2015b), allowing us to  
197 make inferences about environmental suitability for ZIKV transmission in areas where it has yet  
198 to be reported or where we are less certain about its presence. How the ongoing epidemic  
199 unfolds in terms of case numbers (or incidence) will depend on a range of other factors such as  
200 local transmission dynamics, herd immunity, patterns of contact among mosquitoes and

201 infectious and susceptible humans (Stoddard et al. 2013), and mosquito-to-human ratios as  
202 recently shown for dengue (Kraemer et al. 2015a) and chikungunya (Salje et al. 2016).  
203

204 Globally, we predict that over 2.17 billion people live in areas that are environmentally suitable for  
205 ZIKV transmission. We also estimate the number of births occurring in the Americas only, as it is  
206 the region for which the most accurate high-resolution population data on births exists (Tatem et  
207 al. 2014, Sorichetta et al. 2015) and because it is the focus of an ongoing outbreak, which is the  
208 largest recorded thus far. In the Americas alone, an estimated 5.42 million births occurred in  
209 2015 within areas and at times that are suitable for ZIKV transmission. It is important to  
210 recognize that not all individuals will be exposed to ZIKV. Like with other flaviviruses, a ZIKV  
211 outbreak may be temporally and spatially sporadic and, even in the most receptive environments,  
212 is unlikely that all of the population will be infected. Furthermore, increasing herd immunity of this  
213 likely sterilizing infection will rapidly reduce the size of the susceptible population at risk for  
214 infection in subsequent years (Dick, Kitchen and Haddow 1952) and work is ongoing to predict  
215 the likely infection dynamics after establishment. Instead, the estimates are intended as  
216 indicators of the total number of individuals or births that may require protection during the first  
217 wave of the outbreak. Specifically, these populations should be the focus of efforts to increase  
218 awareness and provide guidelines for mitigating personal risk of infection. In future analyses, our  
219 estimates could be extended to include ZIKV incidence and the virus' effect on incidence of  
220 associated conditions such as Guillain-Barré syndrome and microcephaly. Before appropriately  
221 caveated estimates can be generated, however, more information is needed regarding: (i) the  
222 background rate of these conditions due to other causes; (ii) how risk may vary throughout the  
223 course of a pregnancy; (iii) the proportion of the population exposed during outbreaks; and (iv)  
224 whether or not immunity acquired through a mother's prior exposure is protective.  
225

226 For all arboviral diseases, public health education about reducing populations and avoiding  
227 contact with mosquito vectors is required in at-risk areas. Specific to ZIKV is the risk of  
228 microcephaly in newborns, which has led public health agencies to issue warnings for women  
229 who are currently or planning on becoming pregnant in areas suspected to have ongoing ZIKV  
230 transmission and the declaration of a Public Health Emergency of International Concern  
231 (Heymann et al. 2016). Due to the sensitive nature and implications of these warnings, it is  
232 important that levels of risk are rigorously estimated, validated, and updated. Transmission of  
233 related arboviral diseases still occurs in many areas we defined as at-risk for ZIKV, which  
234 highlights the need for improved vector control outcomes, particularly those targeting *Ae. aegypti*.  
235 Predicted levels of risk for ZIKV transmission are potentially helpful for prioritized allocation of  
236 vector control resources, as well as for differential diagnosis and, if a vaccine becomes available,  
237 delivery efforts. It should be noted that instances of ZIKV sexual transmission have been  
238 reported (Patino-Barbosa et al. 2015, Musso et al. 2015, Foy et al. 2011a). We did not  
239 incorporate secondary modes of transmission into the models we described here, but our map  
240 can help inform future discussions about the potential impact of this mode of transmission as its  
241 relative importance becomes better understood.  
242

243 A great deal of basic epidemiological information specific to ZIKV is lacking. As a result,  
244 information must be leveraged from our knowledge about transmission of related arboviruses.  
245 Previous work has focused on mapping other vector borne diseases that share much of the  
246 ecology of Zika, such as DENV (Bhatt et al. 2013) and CHIKV, as well as for its primary vectors,  
247 *Ae. aegypti* and *Ae. albopictus* (Kraemer et al. 2015c). For this reason, temperature suitability for  
248 dengue (Brady et al. 2013, Brady et al. 2014) was entered into the models due to the greater  
249 number of field and laboratory studies available for parameterising this metric for DENV. Until  
250 more studies related to vector competence and temperature constraints on ZIKV transmission to

251 humans are conducted, this is the most accurate indicator of arboviral disease transmission *via*  
252 *Aedes* mosquitoes currently available. Indeed, all other covariates in our models could equally be  
253 applied to mapping DENV and CHIKV, and ZIKV-specific refinements to modelling covariates will  
254 be possible as the disease continues to expand to allow for improvements in future iterations of  
255 the map. The relatively smaller amount of occurrence data available for ZIKV (especially prior to  
256 recent outbreaks) means that this dataset should also be updated with new information as  
257 necessary, leading to a stronger global evidence base and improved accuracy of future maps.  
258 Better understanding of ZIKV transmission dynamics will eventually allow for further cartographic  
259 refinements to be made, such as the differentiation between endemic- and epidemic-prone  
260 areas. Still, all covariates included in the current study have been updated and refined since  
261 (Bhatt et al. 2013), and when combined with the most extensive occurrence database available  
262 for ZIKV, the resulting map we present here is currently the most accurate depiction of the  
263 distribution of environmental suitability for ZIKV. A map highlighting differences in predicted  
264 suitability for both diseases is provided in Figure 2 -- figure supplement 5.  
265

## 266 **Conclusion**

267 In this study, we produced the first global high spatial-resolution map of environmental suitability  
268 for ZIKV transmission to humans using an assembly of known records of ZIKV occurrence and  
269 environmental covariates in a species distribution modelling framework. While it is clear that  
270 much remains to be understood about ZIKV, this first map serves as a baseline for  
271 understanding the change in the geographical distribution of this globally emerging arboviral  
272 disease. Knowledge of the potential distribution can encourage more vigilant surveillance in both  
273 humans and *Aedes* mosquito populations, as well as help in the allocation of limited resources  
274 for disease prevention. Public health awareness campaigns and advice for mitigation of  
275 individual risk can also be focused in the areas we have predicted to be highly suitable for ZIKV  
276 transmission, particularly during the first wave of infection in a population. The maps we have  
277 presented may also inform existing travel advisories for pregnant women and other travellers.  
278 The maps and underlying data are freely available online *via* figshare (<http://www.figshare.com>).  
279

## 280 **Methods**

281 To map environmental suitability for ZIKV transmission to humans, we applied a species  
282 distribution modelling approach to establish a multivariate empirical relationship between the  
283 probability of ZIKV occurrence and the environmental conditions in locations where the disease  
284 has been confirmed. We employed an ensemble boosted regression trees (BRT) methodology  
285 (De'ath 2007, Elith, Leathwick and Hastie 2008), which required the generation of: (i) a  
286 comprehensive compendium of known locations of disease occurrence in humans; (ii) a set of  
287 background points representing locations where ZIKV has not yet been reported; and (iii) a set of  
288 high-resolution globally gridded environmental and socioeconomic covariates hypothesised to  
289 affect ZIKV transmission. The resulting model produces a 5km x 5km spatial-resolution global  
290 map of environmental suitability for ZIKV transmission to humans.  
291

### 292 **Assembly of the geo-referenced ZIKV occurrence dataset**

293 Information about the locations of ZIKV occurrence in humans was extracted from peer-reviewed  
294 literature, case reports, and informal online sources following previously established protocols  
295 (Kraemer et al. 2015b, Messina et al. 2014, Messina et al. 2015a). To collate the peer-reviewed  
296 dataset, literature searches were undertaken using PubMed  
297 (<http://www.ncbi.nlm.nih.gov/pubmed>) and ISI Web of Science (<http://www.webofknowledge.com>)  
298 search engines using the search term "Zika". No language restrictions were placed on these  
299 searches; however, only those citations with a full title and abstract were retrieved, resulting in  
300 the review of 148 references ranging in publication dates between 1951 and 2015. In-house

301 language skills allowed review of all English, French, Portuguese and Spanish articles for  
302 useable location information for human ZIKV occurrence. ProMED-mail  
303 (<http://www.promedmail.org>) was also searched using the term “Zika”, resulting in the review of  
304 139 reports between 27 June 2007 and 18 January 2016. Additionally, the most current database  
305 of ZIKV case locations in Brazil was obtained directly from the Brazilian Ministry of Health. From  
306 all sources, only laboratory confirmation of symptomatic ZIKV infection in humans was entered  
307 into the dataset (mention of suspected cases was not entered). Serological evidence from  
308 healthy individuals could represent a past infection, with transmission potentially occurring in a  
309 different location to that where the individual currently resides (Darwish et al. 1983), or could be  
310 an artefact from possible cross-reactivity with a variety of different viruses (Smithburn et al.  
311 1954). As a result, these less reliable diagnoses of ZIKV were excluded.

312  
313 All available location information was extracted from each peer-reviewed article and ProMED  
314 case report. The site name was used together with all contextual information provided about the  
315 site to determine its latitudinal and longitudinal coordinates using Google Maps  
316 (<https://www.maps.google.com>). If the study site could be geo-positioned to a specific place, it  
317 was recorded as a point location. If the study site could only be identified at an administrative  
318 area level (e.g. province or district), it was recorded as a polygon along with an identifier of its  
319 administrative unit. If imported cases were reported with information on the site of infection, they  
320 were geo-positioned to this site; if imported cases were reported with no information about the  
321 site of infection, they were not entered into the dataset. Informal online data sources were  
322 collated automatically by the web-based system HealthMap (<http://www.healthmap.org>) as  
323 described elsewhere (Freifeld et al. 2008). Alerts for ZIKV were obtained from HealthMap for the  
324 years 2014-2016, and then manually checked for validity. In total, usable location information  
325 was extracted from 110 sources. Information was also collected about the status of symptoms in  
326 each reported occurrence, distinguishing between those where symptomatic cases were being  
327 reported, versus those where only seroprevalence was detected in healthy individuals.

328  
329 Due to the potential for multiple independent reports referring to the same cases temporal and  
330 spatial standardization was required, as we have described previously in detail for dengue  
331 mapping efforts (Messina et al. 2014). In brief, an occurrence was defined as a unique location  
332 with one or more confirmed cases of ZIKV occurring within one calendar year (the finest temporal  
333 resolution available across all records). Point locations were considered to be overlapping if they  
334 lay on the same 5km x 5km pixel, and polygon locations were identified by a unique  
335 administrative unit code. Furthermore, all polygons whose geographic area was greater than one  
336 square decimal degree (approximately 111 square kilometers at the equator) were removed from  
337 the dataset to avoid averaging covariate values over very large areas, and only those  
338 occurrences comprising symptomatic individuals were retained for modelling purposes to ensure  
339 an accurate location of infection. In total, the final occurrence dataset contained 323 unique  
340 occurrences to be entered into our BRT modelling procedure. A map of the final set of  
341 occurrence locations is provided as Figure 1a.

### 342 343 **Generation of the background location dataset**

344 Separate maps of the relative probability of occurrence of *Ae. aegypti* and *Ae. albopictus*  
345 (Kraemer et al. 2015c) were used to compute a combined metric of the relative probability of  
346 vector occurrence, by taking the maximum value from the two layers for all 5km x 5km gridded  
347 cells globally. The inverse of this combined-*Aedes* occurrence probability layer (higher values  
348 indicating greater certainty of absence) was then used to draw a biased sample of 10,000  
349 background locations. As such, a greater number of background points were sampled in areas  
350 where we are more certain that *Ae. aegypti* or *Ae. albopictus* do not occur, and therefore where

351 ZIKV is less likely to be transmitted to humans. While it has been demonstrated that predictive  
352 accuracy from presence-background species distribution models can be improved by biasing  
353 background record locations toward areas with greatest reporting probabilities (Phillips et al.  
354 2009), information on possible reporting biases, or proxies of such spatial bias, are currently  
355 unavailable for ZIKV. These 10,000 background locations were combined with the standardized  
356 occurrence dataset to serve as comparison data locations in the BRT species distribution  
357 modelling procedure. The background locations were weighted such that their total sum was  
358 equal to the total number of occurrence locations (n=237; pseudo-absence weighting=0.0237), in  
359 order to aid in the discrimination capacity of the model (Barbet-Massin et al. 2012).

360

### 361 **Explanatory Covariates**

362 A set of six covariates hypothesized to influence the global distribution of ZIKV transmission to  
363 humans were used in our models to establish an empirical relationship between ZIKV presence  
364 or absence and underlying environmental conditions. These six covariates included: (i) an index  
365 of temperature suitability for dengue transmission to humans *via Ae. aegypti*; (ii) temperature  
366 suitability for dengue transmission to humans *via Ae. albopictus*; (iii) minimum relative humidity;  
367 (iv) annual cumulative precipitation; (v) an enhanced vegetation index (EVI); and (vi) urban  
368 versus rural habitat type. The underlying hypothesis behind each of the covariates is discussed  
369 in more detail below, along with a description of data sources and any processing that was  
370 undertaken before entering these covariates into our models. Maps of each covariate layer are  
371 provided in the supplementary information in Figure 1 -- figure supplement 1.

372

373 *Temperature suitability for dengue transmission to humans via Ae. aegypti or Ae. albopictus:*  
374 Temperature affects key physiological processes in *Aedes* mosquitoes, including age- and  
375 temperature-dependent adult female survival, as well as the duration of the extrinsic incubation  
376 period (EIP) of arboviruses and the length of the gonotrophic cycle (Brady et al. 2013). While  
377 these parameters have yet to be measured experimentally for ZIKV, they have been for the  
378 closely related DENV. We obtained temperature data from WorldClim v1.03  
379 (<http://www.worldclim.org>), which uses historic global meteorological station data from 1961-2005  
380 to interpolate global climate surfaces. MARKSIM software (Jones and Thornton 2000) was then  
381 used to apply the coefficients of 17 Global Climate Models (GCMs) to estimate temperature  
382 values for the year 2015. This enabled us to incorporate the quantified effects of temperature on  
383 DENV transmission into a cohort simulation model that analysed the cumulative effects of both  
384 diurnal and inter-seasonal changes in temperature on DENV transmission within an average  
385 year, both for *Ae. aegypti* and *Ae. albopictus* separately. The models were then applied to the  
386 2015 temperature data for each 5km x 5km grid cell globally. This resulted in maps of  
387 temperature suitability for DENV transmission by either *Aedes* species ranging from 0 (no  
388 suitable days) to 1 (365 suitable days). These measures were then used as a proxy for  
389 temperature suitability for ZIKV transmission to humans.

390

391 *Annual cumulative precipitation:* Presence of static surface water in natural or man-made  
392 containers is a pre-requisite for *Aedes* oviposition and larval and pupal development. While fine-  
393 scale spatial and temporal heterogeneities have been observed between precipitation, vector  
394 abundance, and incidence of human DENV infections, there is evidence that areas with greater  
395 amounts of precipitation are generally associated with higher DENV infection risk (Chandy et al.  
396 2013, Chowell and Sanchez 2006, Dom et al. 2013, Pinto et al. 2011, Restrepo, Baker and  
397 Clements 2014, Sang et al. 2014, Sankari et al. 2012, Campbell et al. 2015). Although studies  
398 that directly connect levels of precipitation to ZIKV transmission have yet to exist, we assumed  
399 for Zika a similar association of precipitation as closely related flaviviruses. WorldClim v1.03

400 precipitation data and MARKSIM software were used as described above for temperature, to  
401 estimate annual cumulative precipitation for the year 2015 for each 5km x 5km grid cell globally.

402

403 *Minimum relative humidity:* Greater relative humidity has been found to promote DENV  
404 propagation in *Ae. aegypti* mosquitoes in several localized settings (Colon-Gonzalez, Lake and  
405 Bentham 2011, Thu, Aye and Thein 1998), and has also been found to be an important  
406 contributor when predicting DENV risk at a global scale (Hales et al. 2002). Therefore, we again  
407 assumed a similar association for ZIKV in the absence of any direct studies, and included the  
408 minimum annual relative humidity in our models as a potential limiting factor to ZIKV  
409 transmission. Relative humidity (RH) was calculated as a percent of saturation humidity, or the  
410 amount of water vapour required to saturate the air given a particular temperature, using the  
411 temperature data from WorldClim v1.03 described earlier. The saturation, or “dew”, point ( $T_{dew}$ )  
412 was calculated using a tabular relationship (Linacre 1977). RH was then calculated as follows:

$$RH = \frac{V(T_x)}{V(T_{dew})} \times 100$$

413

414 Where  $V(T_{dew}) = 611.21 \times \exp(17.502 \times \frac{T}{240.97 + T})$  and  $V(T_x)$  is the humidity at the given  
415 temperature. We then extracted the minimum annual RH for each 5km x 5km pixel globally for  
416 the year 2015.

417

418 *Enhanced Vegetation Index (EVI):* A close association has been shown between local moisture  
419 supply, vegetation canopy development, and abundance of mosquito reproduction (Linthicum et  
420 al. 1999), with previous studies highlighting the importance of moisture-related measures such as  
421 relative humidity to DENV occurrence (Hales et al. 2002). Although resistant to desiccation, both  
422 *Aedes* eggs and adults require moisture to survive (Cox et al. 2007, Sota and Mogi 1992,  
423 Reiskind and Lounibos 2009, Costa et al. 2010, Luz et al. 2008), with low dry season moisture  
424 levels substantially affecting *Aedes* mortality (Russell, Kay and Shipton 2001, Trpis 1972, Luz et  
425 al. 2008). Vegetation canopy cover has previously been associated with higher *Aedes* larvae  
426 density (Fuller et al. 2009, Troyo et al. 2009, Bisset Lazcano et al. 2006, Barrera et al. 2006) by  
427 reducing evaporation from containers, decreasing sub-canopy wind speed, and protecting  
428 outdoor habitats from direct sunlight. To account for these factors, we included a 5km x 5km  
429 resolution measure of the EVI derived from NASA’s Moderate Resolution Imaging Spectrometer  
430 (MODIS) imagery (Wan et al. 2002, Lin 2012), summarized from gap-filled, 8-day, 1km x 1km  
431 resolution images acquired globally for years 2000 through 2014 (Weiss et al. 2014) to produce a  
432 mean annual EVI layer. This mean EVI product is indicative of amount of photosynthesis taking  
433 place in the environment over the course of a year, which is positively correlated with the density  
434 of vegetation, and is thus a proxy for the level of moisture available given the relationship  
435 between precipitation and vegetative growth.

436

437 *Urban versus rural habitat type:* There is a well-established link between urban areas, some  
438 vector borne diseases, and their vectors. In particular, *Ae. aegypti* is found in close proximity to  
439 human dwellings often breeding in artificial containers (Brown et al. 2011, Powell and Tabachnick  
440 2013, Kraemer et al. 2015c). To identify the relationship between urbanisation and ZIKV  
441 presence we adapted probabilistic spatial modelling techniques to predict the spatial distribution  
442 of global urban extents at a 5km x 5km spatial resolution. We used urban growth rates from the  
443 United Nations Population Division (Division 2014), paired with urban extents measured and  
444 tested by the Moderate Resolution Imaging Spectroradiometer Collection 5 (MODIS C5) land-  
445 cover product for Asia (Schneider et al. 2015, Schneider, Friedl and Potere 2009, Schneider,  
446 Friedl and Potere 2010). A set of spatial covariate datasets hypothesized to influence the spatial

447 patterns of urban expansion was generated, including the time to travel from each 5km x 5km  
448 pixel to a major city (Nelson 2008), the proportion of urbanised land within a buffer of 20 km,  
449 human population density (Linard and Tatem 2012, Stevens et al. 2015, Gaughan et al. 2013),  
450 slope (Becker et al. 2009), and distance to water (Arino et al. 2008). A BRT modelling approach  
451 was then used to predict areas that would become urban in 2015 (Linard, Tatem and Gilbert  
452 2013). Outputs were tested against a training dataset comprising points from Asia only, and  
453 showed good overall predictive performance (AUC=0.82). The output raster is a 5km x 5km  
454 gridded surface with urban (1) vs. rural (0) pixels.

455

### 456 **Ensemble Boosted Regression Trees approach**

457 The boosted regression tree (BRT) modelling procedure combines regression trees with gradient  
458 boosting (Friedman 2001). In this procedure, an initial regression tree is fitted and iteratively  
459 improved upon in a forward stagewise manner (boosting) by minimising the variation in the  
460 response not explained by the model at each iteration. It has been shown to fit complicated  
461 response functions efficiently, while guarding against over-fitting by use of extensive internal  
462 cross-validation. As such, this approach has been successfully employed in the past to map  
463 dengue and its *Aedes* mosquito vectors, as well as other vector-borne diseases (Bhatt et al.  
464 2013, Pigott et al. 2014b, Messina et al. 2015b, Kraemer et al. 2015c). To increase the  
465 robustness of model predictions and quantify model uncertainty, we fitted an ensemble (Araújo  
466 and New 2007) of 300 BRT models to separate bootstraps of the data. We then evaluated the  
467 central tendency as the mean across all 300 BRT models (Bhatt et al. 2013). Each of the 300  
468 individual models was fitted using the `gbm.step` subroutine in the `dismo` package in the R  
469 statistical programming environment (Elith et al. 2008). All other tuning parameters of the  
470 algorithm were held at their default values (tree complexity= 4, learning rate= 0.005, bag  
471 fraction= 0.75, step size= 10, cross-validation folds=10). Each of the 300 models predicts  
472 environmental suitability on a continuous scale from 0 to 1, with a final prediction map then being  
473 generated by calculating the mean prediction across all models for each 5km x 5km pixel. Cross-  
474 validation was applied to each model, whereby ten subsets of the data comprising 10% of the  
475 presence and background observations were assessed based on their ability to predict the  
476 distribution of the other 90% of records using the mean area under the curve (AUC) statistic. This  
477 AUC value was then averaged across the ten sub-models and finally across all 300 models in the  
478 ensemble in order to derive an overall estimate of goodness-of-fit. Additionally, to avoid AUC  
479 inflation due to spatial sorting bias, a pairwise distance sampling procedure was used, resulting  
480 in a final AUC which is lower than would be returned by standard procedures but which gives a  
481 more realistic quantification of the model's ability to extrapolate predictions to new regions  
482 (Wenger and Olden 2012). We restricted our models to make predictions only within areas where  
483 either *Ae. aegypti* probability of occurrence (Kraemer et al. 2015c) is more than 0.8 or  
484 temperature is conducive to transmission for at least 355 days in an average year. A second  
485 ensemble of 300 models was executed which did not take into account temperature suitability for  
486 dengue transmission *via Ae. albopictus*, due to the uncertainty of this species as a competent  
487 ZIKV vector. The results of this ensemble of models are provided in Figure 2 -- figure supplement  
488 3.

489

### 490 **Population and births at risk**

491 To calculate the number of people located in an area that is at any level of risk for ZIKV  
492 transmission, the global ZIKV environmental suitability map was combined with fine-scale global  
493 population surfaces (SEDAC 2015, WorldPop 2015). Firstly, the continuous ZIKV environmental  
494 suitability map (ranging from 0 to 1) was converted into a binary surface indicating whether there  
495 is any risk of transmission. To do this, we carried out a protocol previously used in (Pigott et al.  
496 2015a), choosing a threshold environmental suitability value that encompasses 90% of the ZIKV

497 occurrence point locations. This threshold cut-off of 90% was chosen (rather than 100%) to  
498 reflect potential errors or inaccurate locations in the occurrence point dataset. Every 5km x 5km  
499 pixel in the suitability map with a value above this threshold value was considered at risk for ZIKV  
500 transmission. Finally, to estimate the population at risk, we multiplied this binary ZIKV risk map  
501 by the global population counts (aligned and aggregated to the same 5km x 5km grid) for the  
502 year 2015 and summed across all cells.

503

504 We next estimated the maximum number of births potentially affected by ZIKV in Latin America,  
505 as this region is the focus of the recent outbreak and the first to point to a possible association  
506 with microcephaly in newborn infants to mothers infected with ZIKV. In order to do this, we first  
507 identified the proportion of the year that is suitable for ZIKV transmission within areas that are  
508 predicted to be suitable in the binary ZIKV risk map. This proportion was derived from existing  
509 temperature suitability models (Brady et al. 2014, Brady et al. 2013), which predict the total  
510 number of days within an average year that arbovirus transmission can be sustained in *Ae.*  
511 *aegypti*, assuming there is a local human reservoir of infection. While the intra-mosquito viral  
512 dynamics in this model were parameterised for dengue virus, the limited information currently  
513 available on other arboviruses suggests that their dynamics are similar (Lambrechts et al. 2011).  
514 Using the resulting 5km x 5km map showing the proportion of the year suitable for ZIKV  
515 transmission to humans, we then multiplied this by a map (also at a 5km x 5km resolution) of the  
516 number of births in the Americas for the year 2015, updated from (Tatem et al. 2014, UNFPA  
517 2014). The resulting map indicates the number of births in the Americas potentially at risk for  
518 ZIKV (for 2015), assuming ZIKV currently fully occupies its environmental niche and that births  
519 are evenly distributed throughout the year.

## 547 **Figure Legends**

548

549 Figure 1: (a) Map showing the distribution of the final set of 323 ZIKV occurrence locations  
550 entered into the ensemble Boosted Regression Tree modelling procedure. Locations are  
551 classified by year of occurrence to show those which took place (i) prior to the 2007 outbreak in  
552 Federated States of Micronesia; (ii) between 2007-2014; and (iii) during the 2015-2016 outbreak;  
553 (b) the total number of locations reporting symptomatic ZIKV occurrence in humans globally over  
554 time.

555

556 Figure 2: Maps of (a) global environmental suitability for ZIKV, ranging from 0 (grey) to 1 (red),  
557 showing greater detail for (b) the Americas, (c) Africa, and (d) Asia and Oceania.

558

559 Figure 3: Status of ZIKV reporting as of 2016 by country, showing countries that are highly  
560 environmentally suitable (having a suitable area of more than 10,000 square kilometres) but  
561 which have not yet reported symptomatic cases of ZIKV in humans. “Currently reporting”  
562 countries are those having reported cases since 2015.
